Abstract—In this paper, we present a surface acoustic wave (SAW) gas sensor based on nano-structured molybdenum oxide (MoOₓ) thin film. The film was deposited onto a 36° YX LiTaO₃ SAW transducer, with an operating frequency of approximately 103 MHz, by thermal evaporation. The nanostructured MoOₓ film consists of connected nanorods with diameters of less than 10 nm. We compared devices with MoOₓ deposited by RF sputtering and thermal evaporation and found those with evaporated films have response that are an order of magnitude larger.

I. INTRODUCTION

Transition metal oxides such as molybdenum oxide (MoOₓ) have been widely studied for application as catalyst, electrochromic and energy storage devices, and chemical sensors. MoOₓ crystallites have layered structures with an orthorhombic structure and are an n-type semiconducting with a band gap of 3.2 eV in its bulk form. Its sheet resistance is in the order of 10¹⁰ Ωm at room temperature. MoOₓ is a highly reactive material that can easily be reduced at elevated temperatures, making it an excellent candidate for gas sensing applications. Despite its promising properties as a catalyst, only recently has it attracted interest as an active element for gas sensing applications. MoOₓ have been found to be very sensitive to various gases such as NO, NO₂, CO, H₂ and NH₃ [1-5].

Thermal evaporation is one of the most widely employed techniques for depositing nanostructured thin films [7]. The melting point of MoOₓ is less than 800°C, making it an attractive material for thin film deposition by thermal evaporation. MoOₓ nanostructured thin films pass increased sensitivity comparing with their bulk counterparts due to large surface to volume ratio, Debye lengths (which is comparable to their lateral dimensions) and their greater level of crystallinity reduces possible instabilities [8]. In this paper, the preparation of MoOₓ nanostructured thin films and their H₂ gas sensing performance are reported.

II. EXPERIMENTAL

A. Transducer fabrication

In this work, a 36° YX LiTaO₃ SAW device is used as the transducing platform. It consists of a two-port resonator with 38 electrode pairs in input and output inter-digital transducers (IDTs), 160 electrodes in each reflective array, 700 μm aperture width and a periodicity of 40 μm. A two-port resonator structure was chosen over a delay line as its higher phase slope increases oscillation stability. The IDTs and reflectors were formed by pattering an 80 nm Au layer. The Au layer was deposited upon 20 nm Ti for improved adhesion to the substrate.

B. Molybdenum Oxide Synthesis

The vapor-phase growth of crystalline MoO₃ was conducted in a horizontal tube electric furnace. The furnace structure and experimental setup are depicted in Fig. 1. The growth chamber comprised of a fused quartz tube. The growth process can be briefly summarized as follows: the as-received MoO₃ powder was loaded on a Si plate (approximately 1 g in each run), which was located in the heating zone of furnace. Another Si plate, which served as the growth zone, was placed at a distance of 5 cm from the MoO₃ source powder. Temperatures of the source and the growth zone were measured with K-type thermocouple. During the growth process, the purified air at a flow rate of 15.0 l/h was introduced into the quartz tube and the MoO₃ source was held at constant temperatures of 500, 600, 650 and 700°C for various time lengths (1-12 hrs). Crystalline MoO₃ was grown on the growing plate where the temperature gradient was about 10-12 °C/cm from the center of the furnace. After the deposition process, the crystallographic structure of the grown MoO₃ was investigated by X-ray diffraction (XRD, Bruker D8 Advance) using an X-ray generator operated at 40 kV/35 mA with Cu Kα radiation λ=1.5418 Å at a scanning rate of 1 °/min. The morphology of the crystals was studied using a field emission scanning electron microscope SEM (JSM-6700 F, JEOL Inc.).

MoO₃ has two basic polytypes, the first is orthorhombic (α-type), which is a thermo-dynamically stable phase, and the second is metastable monoclinic (β-type), which has a ReO₃-type structure. The most important structural characteristic of α-MoO₃ is its structural anisotropy, where highly asymmetrical MoO₃ octahedra are interconnected with their edges along [001] direction. They are interlinked with their corners along [100], resulting in a so-called double-layer planar structure. An alternate stack of these
double-layered sheets along [010] will lead to the formation of α-MoO₃, where van der Waals interactions are the major binding means among the piled sheets. A schematic illustration of synthetic platelet-like MoO₃ nanorod is shown in Fig 2.

Prior to depositing the nanostructured MoO₃ on the SAW transducers, a number of deposition trials were conducted in a cylindrical oven with a center temperature in a range from 400°C to 900°C. The samples were placed in a location where the ambient temperature was approximately 100°C to 200°C less than the temperature at the center of the furnace.

In this vapor-solid mechanism, the shape and the size of the MoO₃ nanorods are dependent on the crystal orientation of the substrates, as well as the reaction parameters during the deposition process. The SEM micrographs (Figs. 3 and 4) indicate that the shape of the crystallites of these nanostructures strongly depend on their location in the furnace and the temperature. The platelet-like MoO₃ nanoplates were grown on LiTaO₃ substrate with a well-defined crystalline orientation, as shown in Fig 3. An SEM image of the nanostructured thin film that was chosen as the sensitive layer is shown in Fig 4. This film was deposited at a temperature of 400°C. Its structure consists of fine connected plates, whose surface to volume ratio was the largest of all the films deposited. The low deposition temperature utilized for this film is also important, as at high temperatures the LiTaO₃ substrate loses its piezoelectric properties.
III. RESULTS

After the deposition of the thin films, the sensor was placed in a multi-channel gas system and exposed to different concentrations of \( \text{H}_2 \) gas. The dynamic performance of the sensor at different concentrations of \( \text{H}_2 \) at 265°C is shown in Fig. 6. The sensor response (the variation in operating frequency of oscillation due to the interaction with the target gas) for temperatures in a range of 200 to 400°C is shown in Fig. 7. The largest response was obtained at approximately 285°C, yet the most stable responses were obtained at approximately 265°C.

IV. CONCLUSIONS

In summary, vapor transport has been employed to synthesize crystalline MoO\(_3\) nanostructured thin films from MoO\(_3\) powder. Such films were deposited using a vapor-solid process on a 36° YX LiTaO\(_3\) device to develop a gas sensor. The sensor was tested for different concentrations of \( \text{H}_2 \) gas in synthetic air at elevated temperatures in the range of 200 to 400°C. A large and stable response to \( \text{H}_2 \) was obtained. This work shows the potential of the MoO\(_3\) nanostructure for the development of gas sensitive thin films.
