**Abstract**

A new kinetically preferable polymorph of 1-(4'-cyanobenzyl)pyridinium bis(maleonitriledithiolato)nickelate ( $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>]) was achieved and characterized by element microanalysis for C, H and N elements, powder X-ray diffraction (PXRD) and differential scanning calorimetry (DSC) techniques.  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] shows a magnetostructural phase transition together with a thermal anomaly at  $\sim$ 192 K. In high-temperature phase (HTP), the  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] crystal belongs to monoclinic space group  $P2_1/c$ , and its asymmetric unit is comprised of one pair of CN-Py<sup>+</sup> and [Ni(mnt)<sub>2</sub>]<sup>-</sup> ions. Both CN-Py<sup>+</sup> and [Ni(mnt)<sub>2</sub>]<sup>-</sup> ions form uniform columnar stacks, respectively. In low-temperature phase (LTP), the space group of the crystal is lowered to triclinic  $P-1$ , its asymmetric unit changes into two pairs of anions and cations, moreover, both stacks of CN-Py<sup>+</sup> and [Ni(mnt)<sub>2</sub>]<sup>-</sup> ions are dimerized.  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] features an  $S = \frac{1}{2}$  Heisenberg regular antiferromagnetic (AFM) linear chain system with  $|J| = 86(9)$  K in HTP, while a spin gap is opened with  $\Delta = 568$  K in LTP. The magnetic phase transition in  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] shows the spin-Peierls transition characters from the changes of both crystal structures and magnetic natures.

**Keywords:** Nickel-bis-dithiolene, polymorph, spin-Peierls-type transition, symmetry breaking phase transition

## Introduction

Polymorphism means that a solid shows different crystalline forms or crystallized structures, which generally have various thermal stabilities and physicochemical properties but with the same components. A crystallization process includes the nucleation of the first crystallites and the growth of crystalline phase; and the formation of different polymorphs is dependent on the initial nucleation process. Many researchers have made tremendous efforts to deeply understand the polymorphism phenomenon,<sup>1-4</sup> which lead to significant progress being achieved in the crystal engineering of polymorph up to now.<sup>5,6</sup> However, it still remains challenging to predict and control the different forms emerging for a solid at present stage owing to the initial nucleation process being hard surveyed.<sup>7-10</sup>

The crystal structure generally determines the properties of a matter, and thus, different polymorphisms often show distinct functionalities, probably leading to different technological applications.<sup>11,12</sup> In a molecule crystal, the molecule packing fashion is strongly influenced by intermolecular weak interactions, including  $\pi\cdots\pi$  stacking, C-H $\cdots\pi$ , H-bonding or S $\cdots$ S, S $\cdots$ N, S $\cdots$ C, halogen $\cdots$ halogen and van der Waals interactions etc. Since the different arrangements show small energy differences in molecule crystals, the polymorphism is a common phenomenon, especially, in the crystals with planar  $\pi$ -conjugated molecule architectures, e.g., a charge-transfer salt [4'-CF<sub>3</sub>bzPy][Ni(mnt)<sub>2</sub>], in which 4'-CF<sub>3</sub>bzPy<sup>+</sup> and mnt<sup>2-</sup> correspond respectively to 1-(4'-trifluoromethylbenzyl)pyridinium and maleonitriledithiolate, crystallizes in two types of polymorphs,<sup>13, 14</sup> amongst them one crystal form shows mixed stack of anion and cation with a hysteretic magnetic transition at 159/208 K on cooling/heating;<sup>13</sup> another crystal form has separately stacks of anions and cations, undergoing two hysteretic magnetic phase transitions in a narrow temperature region (190–217 K).<sup>14</sup> The molecule materials with hysteretic effect show intrinsically memory effect to have promising applications in the areas of information storage etc.<sup>15-18</sup>

Spin-Peierls transition is an interesting phenomenon in the low-dimensional spin systems, theoretically predicted by R. E. Peierls in 1955.<sup>19</sup> A one-dimensional (1D)

1  
2  
3  
4 Heisenberg  $S = \frac{1}{2}$  regular AFM linear chain is a thermodynamic unstable spin system  
5  
6 with respect to the dimerized chain, the spin chains dimerize at a certain temperature  
7  
8 and at this transition the matter undergoes a second-order transition to reach a singlet  
9  
10 ground state with a magnetic gap, moreover, the magnetic gap progressively increases  
11  
12 with lowering temperature and reaches to the maximum at the absolute zero Kelvin.  
13  
14 The driving force of spin-Peierls transition is magnetic-lattice interaction.  
15  
16 Experimentally, a spin-Peierls transition was firstly found in a charge-transfer salt,  
17  
18 [TTF][CuS<sub>4</sub>C<sub>4</sub>(CF<sub>3</sub>)<sub>4</sub>] where TTF<sup>+</sup> = tetrathiafulvalinium and [S<sub>2</sub>C<sub>2</sub>(CF<sub>3</sub>)<sub>2</sub>]<sup>2-</sup> =  
19  
20 cis-(1,2-perfluoromethylethylene-1, 2-dithiolato).<sup>20</sup> Since then, several families of  
21  
22 charge-transfer salt-based<sup>21-27</sup> and inorganic<sup>28-30</sup> spin-Peierls systems have been  
23  
24 reported in succession.

25  
26 In previous study, we harvested one crystal form of charge-transfer salt  
27  
28 [CN-Py][Ni(mnt)<sub>2</sub>], where the CN-Py<sup>+</sup> denotes 1-(4'-cyanomethylbenzyl)pyridinium  
29  
30 and this crystalline form is labeled as  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>].<sup>31</sup>  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>]  
31  
32 features a 1D Heisenberg  $S = \frac{1}{2}$  regular AFM chain system, but shows complicated  
33  
34 magnetic behaviors, including that a magnetic transition occurs at  $\sim 190$  K, leading to  
35  
36 spin gap ( $\Delta \approx 614$  K) opening in LTP, and the canted spin anti-ferromagnetism  
37  
38 appears in the low temperature at 2 K with a clearly magnetic hysteresis. However,  
39  
40 the temperature dependent single crystal structure and PXRD analyses demonstrated  
41  
42 that no crystal structure phase transition undergoes at  $\sim 190$  K. Moreover, there is no  
43  
44 thermal anomaly at  $\sim 190$  K in the DSC plot. The observation that a Heisenberg  $S = \frac{1}{2}$   
45  
46 regular AFM chain system with a magnetic transition and a spin gap is rather  
47  
48 interesting phenomenon.<sup>31</sup>

49  
50 In this work, we further obtained a new polymorph of [CN-Py][Ni(mnt)<sub>2</sub>], which  
51  
52 shows segregate cation and anion stacks with a spin-Peierls-type transition at  $\sim 192$  K,  
53  
54 and this new crystal form is labeled as  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>]. The calculation for the  
55  
56 total energy of per unit cell revealed that  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] is more stable phase in  
57  
58 thermodynamics, while  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] is kinetically preferred form. In addition,  
59  
60 the crystal structures and magnetic behaviors in both HTP and LTP are explored for  
 $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] in detail.

## Experimental section

### Chemicals and materials

The reagents and chemicals used in this study were purchased from commercial sources. The starting material,  $\text{Na}_2\text{mnt}$ ,<sup>32</sup>  $[\text{CN-Py}]\text{Br}$  and  $[\text{CN-Py}]_2[\text{Ni}(\text{mnt})_2]$ <sup>31</sup> were prepared following the literature approaches.

### Formation and growth of $\beta$ - $[\text{CN-Py}][\text{Ni}(\text{mnt})_2]$ Crystals

The  $\text{I}_2$  (150 mg, 0.59 mmol) dissolved in 10  $\text{cm}^3$  methanol was added drop-by-drop into the methanol solution (20  $\text{cm}^3$ ) containing  $[\text{CN-Py}]_2[\text{Ni}(\text{mnt})_2]$  (730 mg, 1.0 mmol), and this mixture was stirred for 15 minutes and then stood overnight. The black microcrystals were filtered off. Noticeably, these microcrystals were not washed using any solvent, but directly dissolved in  $\text{MeCN}/\text{Me}_2\text{CO}$  to give the solution, and such type of solution was evaporated at ambient temperature for 6-8 days to yield  $\beta$ - $[\text{CN-Py}][\text{Ni}(\text{mnt})_2]$  crystals, and these crystals are suitable to be used for the collection of single crystal X-ray diffraction data. Otherwise, only  $\alpha$ - $[\text{CN-Py}][\text{Ni}(\text{mnt})_2]$  crystals were obtained. The  $\beta$ - $[\text{CN-Py}][\text{Ni}(\text{mnt})_2]$  crystals were separated using suction, washed with small amount of methanol and dried under vacuum at room temperature. Yield: ca. 87% calculated on the reactant  $[\text{CN-Py}]_2[\text{Ni}(\text{mnt})_2]$ . Elemental microanalysis calculated for  $\text{C}_{21}\text{H}_{11}\text{N}_6\text{NiS}_4$ : C, 47.21; H, 2.08; N, 15.73%. Found: C, 47.14; H, 2.05; N, 15.67%.

The phase purity of both  $\alpha$ - $[\text{CN-Py}][\text{Ni}(\text{mnt})_2]$  and  $\beta$ - $[\text{CN-Py}][\text{Ni}(\text{mnt})_2]$  was examined by PXRD technique (ref. Figure S1).

### Chemical characterization and physical measurements

Elemental analyses (C, H and N) were performed with an Elementar Vario EL III analytical instrument. PXRD data were collected on a Bruker D8 Advance powder diffractometer operating at 40 kV and 40 mA for Cu  $K\alpha$  radiation with  $\lambda = 1.54018 \text{ \AA}$ . Polycrystalline samples were used for this measurement and the  $2\theta$  scan ranges from 5 to  $50^\circ$  with  $0.02^\circ/\text{step}$  and  $1.2 \text{ s/step}$ . DSC measurement was carried out using a DSC Q2000 V24.10 Build 122 for polycrystalline sample in 100-298 K, with a temperature scanning rate of  $10 \text{ K}\cdot\text{min}^{-1}$ . Magnetic susceptibility data were recorded for polycrystalline samples in 1.8-300 K using a Quantum Design MPMS-5S

1  
2  
3  
4 superconducting quantum interference device (SQUID) magnetometer and the molar  
5 magnetic susceptibility  $\chi_m$  of  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] is calculated using one [Ni(mnt)<sub>2</sub>]-  
6 anion per formula unit and the diamagnetism was not removed from the experimental  
7 data.  
8  
9

### 10 11 **X-ray single crystallography**

12  
13 The single-crystal X-ray diffraction data were collected at 296 and 105 K for  
14  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>], respectively, utilizing the graphite monochromated Mo K $\alpha$  ( $\lambda =$   
15 0.71073 Å) on a Bruker-SMART CCD area detector. Diffraction data reductions and  
16 absorption corrections were made using the SAINT and SADABS software  
17 packages,<sup>33</sup> respectively. Crystal structures were solved by means of direct method  
18 using the SHELXL-2014/7 software package,<sup>34</sup> and the non-hydrogen atoms were  
19 anisotropically refined using the full-matrix least-squares method based on F<sup>2</sup>. All  
20 hydrogen atoms were placed at their calculated positions, which were refined using  
21 the riding model on the bound atoms. The crystal of  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] is easily  
22 cracked when it was cooled from HTP to LTP. Fortunately, the single-crystal X-ray  
23 diffraction data were collected for  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] at 105 K as the single crystal  
24 was slowly cooled at a rate of 1 Kelvin per ten minutes and the crystal structure in  
25 LTP was then determined. The final cif file was checked by TwinRotMat in Platon  
26 program,<sup>35</sup> indicating that the high quality single crystal in HTP changes into a  
27 (non)Merohedral Twinning in LTP, with total number of 9981 reflections in HKLF 5  
28 file, in which the number of Twin Contribution reflections are 2039 and the estimated  
29 BASF Line = 0.35. The (non)Merohedral Twinning leads to the refinement  
30 parameters, such as R<sub>σ</sub>, R<sub>1</sub> and wR<sub>2</sub> etc. being slight high in LTP.  
31  
32

33 The single crystal X-ray diffraction data collection, structure refinements and  
34 crystallography are summarized in Table 1 for  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] in both HTP and  
35 LTP. For the sake of benefiting comparison, the single crystal X-ray diffraction data  
36 were re-collected for  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] at 296 K, and the details on the diffraction  
37 data collection, structure refinements and crystallography in this work and in the  
38 literatures<sup>31</sup> are summarized in Tables S1 and S2.

### Crystal structure optimization

Crystal structure optimizations and the total energy calculations were performed for both  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] and  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] in HTP. All calculations

were made in the Density Functional Theory (DFT) framework using the Cambridge Sequential Total Energy Package (CASTEP) module,<sup>36,37</sup> and the Generalized Gradient Approximation (GGA) with Perdew-Burke-Ernzerhof (PBE)<sup>38</sup> exchange-correlation functional is used for the calculations. The starting crystal structures used for the geometry optimization were directly taken from the single crystal data of  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] and  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] at 296 K, respectively; the coordinates of all atoms are optimized but the unit cell is fixed. The bond lengths and bond angles in both moieties of anion and cation, from the optimized crystal structures, are summarized in Tables S3-S6 for  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] and  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>], which match well with the corresponding values acquired from the single crystal X-ray diffraction analyses for  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] and  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] at 296 K. The total energy per unit cell was then calculated based on the optimized crystal structures. In the DFT calculations, the electrons in the Ni (3d<sup>8</sup>4s<sup>2</sup>), S (3s<sup>2</sup>3p<sup>4</sup>), N(2s<sup>2</sup>2p<sup>3</sup>) and C (2s<sup>2</sup>2p<sup>2</sup>) orbitals are treated as the valence electrons, the quality of calculations was set to fine as implemented in the CASTEP and other calculating parameters were set as the default values in the CASTEP code.

## Results and discussion

### Crystal structures of $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>]

$\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] crystallizes in monoclinic system with space group  $P2_1/c$  in HTP. As displayed in Figure 1a, an asymmetric unit is comprised of one pair of anion and cation. The [Ni(mnt)<sub>2</sub>]<sup>-</sup> anion shows planar structure and the CN-Py<sup>+</sup> cation displays the  $\Lambda$ -shaped conformation of molecule. As listed in Table S1, the bond lengths and bond angles in both cation and anion are comparable to the values in  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>].<sup>31</sup> The mean-molecule plane in the [Ni(mnt)<sub>2</sub>]<sup>-</sup> moiety, defined through four coordination sulfur atoms, is roughly parallel to the phenyl ring in the CN-Py<sup>+</sup> with a dihedral angle of 10.2° at 296 K in HTP. The orientation of long molecule axis in the anion is nearly parallel to the C-C $\equiv$ N part in the cation (ref. Figure 1b and 1c), such a type of relative arrangement between the cation and anion in  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] is distinction from that in  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>], where the orientation of long molecule axis in the anion is roughly perpendicular to the C-C $\equiv$ N

part in the cation (ref. Figures 1e and 1f).

As depicted in Figure 1b, the cations and anions are arranged into segregated stacks along the *c*-axis; each stack has two cations or two anions per unit (Figure 1c). The cation and anion stacks show alternative arrangement along *a*- and *b*-axes, leading to each anion stack being enclosed by four cation stacks and vice versa (ref. Figure 1b). The relative slippage are observed in an anion stack along the long molecule axis of anion and slight rotation between two superimposed anions, and this type of arrangement offers an efficient way to reduce the electrostatic repulsions between the adjacent  $[\text{Ni}(\text{mnt})_2]^-$  ions. The adjacent  $[\text{Ni}(\text{mnt})_2]^-$  ions show the exact equidistances of Ni...Ni, S(i)...S(i), N(i)...N(i) and C(i)...C(i) (*i* = 1-4) within a stack.<sup>39</sup>

In a stack, the adjacent cations are arranged in a boat-type manner, the phenyl rings are nearly parallel to each other, and the CN groups in the phenyl rings point towards the pyridyl ring of the adjacent cation, indicating that there may exist the CN... $\pi$  interaction<sup>40</sup> between the CN groups with lone electrons pair in the phenyl rings and neighboring electron-deficient pyridyl rings. The adjacent cations have the exact equal distance of centroid-to-centroid of the phenyl rings in a cation stack (Figure S2) for the same reason as that described in the case of anion stack.<sup>39</sup> In addition, it is clearly that there exist charge-assisted hydrogen bonds between cations and anions, which is shown in Figure 1d.

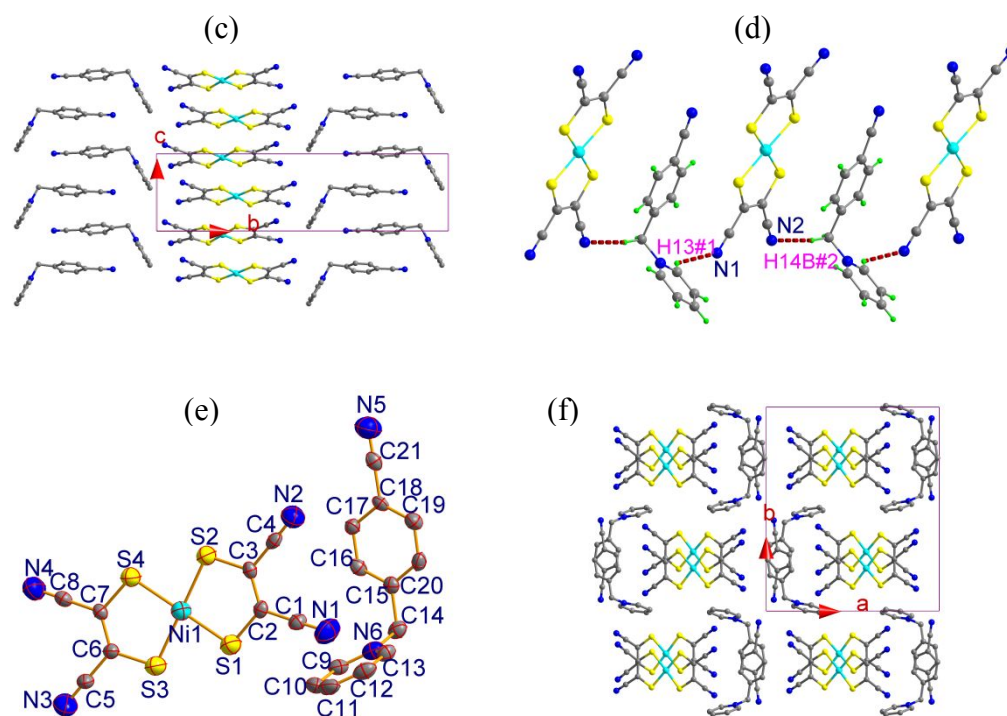

Figure 1: (a) An asymmetry unit containing the labeling of non-hydrogen atoms and the displacement ellipsoids set at the 50% probability level (b, c) packing structures viewed along  $c$ - and  $a$ -axis (d) charge-assisted hydrogen bonds between cations and anions in the crystal structure of  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] at 296 K in HTP. (e) An asymmetry unit with labeling of non-hydrogen atoms and the displacement ellipsoids set at the 50% probability level and (f) packing structure viewed along  $c$ -axis in  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] at 296 K in HTP.

A structure phase transition undergoes at  $\sim 192$  K in  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>], and the details will be discussed in the next section. From HTP to LTP, the space group degrades from  $P2_1/c$  to  $P-1$ , indicating that the phase transition occurring in  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] shows the symmetry broken character from the macroscopic point of view, while the  $Z$  value remains the same ( $Z = 4$ ) as that in HTP. Space group  $P2_1/c$  corresponds to the crystallographic point group  $C_{2h}$ , which has four symmetry elements ( $E$ ,  $C_2$ ,  $i$  and  $\sigma_h$ ), and space group  $P-1$  corresponds to the crystallographic point group  $C_i$  with two symmetry elements ( $E$  and  $i$ ). From HTP to LTP, both the two-fold screw axis and the glide plane disappear, and this leads to the molecules (anions/cations) related by the two-fold screw axis and the glide plane being

1  
2  
3  
4 difference in a unit cell in LTP, accordingly, an asymmetric unit changes from one  
5 pair of cation and anion in HTP to two pairs of cations and anions in LTP (Figure 2).  
6  
7 The bond lengths and bond angles in the cation and the anion in LTP are rather  
8 similar to those in HTP, demonstrating that the symmetry broken structure phase  
9 transition only changes the packing structure but not affect the molecule structures of  
10 both anion and cation in  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>]. Interestingly, a magnetic phase  
11 transition occurs at ~190 K in  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>],<sup>31</sup> nevertheless, the space groups  
12 are the same ( $P2_1/c$ ) in the phases below and above the critical temperature of  
13 magnetic phase transition, moreover, as shown in Figure S3, both cation and anion  
14 stacks still maintain regular in LTP, and no crystal structure phase transition is related  
15 to the magnetic phase transition.

46 The symmetry-broken phase transition results in the distortion of both anion and  
47 cation stacks, and the alteration of stacks can be found from the characteristic  
48 interatom separations, such as the Ni...Ni (denoted as a1 and a2), S...S (represented  
49 as b1-b8) and Ni...S (indicated as c1-c8) distances between the adjacent anions in a  
50 stack (ref. Figure 3a and Table 1); the centroid-to-centroid distances between the  
51 adjacent phenyl rings (denoted as d1 and d2) and the distances of the CN group to the  
52 center of pyridyl ring (illustrated as h1 and h2) in a stack (ref. Figure 3b and Table 1)  
53 as well as the charge-assisted hydrogen-Py bond distances between the cations and the

anions (ref. Figure 4 and Table 3). Since  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] and  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] phases exhibit different stacking structures, as depicted in Figure 4 and Figure S4, they show diverse charge-assisted hydrogen bond networks constructed between anions and cations.

Figure 3: Characteristic distances which demonstrate the distortions of anion and cation stacks in  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] from HTP to LTP (a) the Ni...Ni, Ni...S and S...S separations in an anion stack (b) the centroid-to-centroid separations of neighboring phenyl rings and the distances of CN group to the centroid of pyridyl ring in a cation stack.

### Selectivity of crystalline phase formation and growth

Both  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] and  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] crystals are achievable by means of solvent evaporation the solution of [CN-Py][Ni(mnt)<sub>2</sub>] in MeCN/Me<sub>2</sub>CO at ambient condition. It is worth pointing out that, merely  $\alpha$ -[CN-Py][Ni(mnt)<sub>2</sub>] crystals were obtained if the pure sample of [CN-Py][Ni(mnt)<sub>2</sub>] was used to prepare the solution for crystals growth; the formation and growth of  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] crystals are available only using the solution of [CN-Py][Ni(mnt)<sub>2</sub>] in MeCN/Me<sub>2</sub>CO,

1  
2  
3  
4 which was made by directly using the microcrystalline sample of [CN-Py][Ni(mnt)<sub>2</sub>]  
5 freshly prepared by I<sub>2</sub> oxidizing [CN-Py]<sub>2</sub>[Ni(mnt)<sub>2</sub>], most importantly, not washed by  
6 any solvent. This finding demonstrates that some unknown species, as the structure  
7 directing agent, plays a crucial role in the nucleation process of β-[CN-Py][Ni(mnt)<sub>2</sub>]  
8 crystals. The unknown structure directing agent is probably one of the ions in the  
9 solution, including I<sup>-</sup>, I<sub>3</sub><sup>-</sup>, CN-Py<sup>+</sup> or others. To understand what is the mystical  
10 structure directing agent in the formation of β-[CN-Py][Ni(mnt)<sub>2</sub>] crystals, we  
11 re-dissolved the pure β-[CN-Py][Ni(mnt)<sub>2</sub>] crystals in MeCN/Me<sub>2</sub>CO to get the  
12 solution, meanwhile, a small amount of [CN-Py]I or [CN-Py]I<sub>3</sub> was added in the  
13 solution. Unfortunately, all of the crystals, grew by evaporating the mentioned-above  
14 solution at ambient condition, are in α-[CN-Py][Ni(mnt)<sub>2</sub>] phase.

15  
16 To gain deeper insight into the selectivity of crystalline phases, the crystal  
17 structures of both α-[CN-Py][Ni(mnt)<sub>2</sub>] and β-[CN-Py][Ni(mnt)<sub>2</sub>] phases were  
18 theoretically optimized using the CASTEP three-dimensional periodic system  
19 computational package, while the unit cell parameters were fixed; and the starting  
20 crystal structure models were directly taken from the single crystal X-ray diffraction  
21 data of both α-[CN-Py][Ni(mnt)<sub>2</sub>] and β-[CN-Py][Ni(mnt)<sub>2</sub>] at 296 K. As listed in  
22 Tables S3-S6, the bond lengths and bond angles in the anion and cation moieties  
23 obtained from structure optimization are in agreement well with those found from  
24 single crystal structures of both α-[CN-Py][Ni(mnt)<sub>2</sub>] and β-[CN-Py][Ni(mnt)<sub>2</sub>] at  
25 296 K. On basis of the optimized crystal structures, the whole energy of per unit cell  
26 was calculated for α-[CN-Py][Ni(mnt)<sub>2</sub>] (-30065.05 eV) and β-[CN-Py][Ni(mnt)<sub>2</sub>]  
27 (-30064.56 eV), demonstrating that the α-[CN-Py][Ni(mnt)<sub>2</sub>] phase is  
28 thermodynamically stable crystal form and the β-[CN-Py][Ni(mnt)<sub>2</sub>] phase is  
29 kinetically favorable one. The energy difference between two polymorphs is 11.82 kJ  
30 mol<sup>-1</sup>, indicating that two polymorphs show small energy difference.

### 31 32 33 34 35 36 37 38 39 40 41 42 43 44 45 46 47 48 49 50 51 52 53 54 **Magnetic and phase transition features**

55  
56 Plot of  $\chi_m$  vs. T is depicted in Figure 5a for β-[CN-Py][Ni(mnt)<sub>2</sub>], where  $\chi_m$   
57 denotes the molar magnetic susceptibility with one [Ni(mnt)<sub>2</sub>]<sup>-</sup> anion per formula unit  
58 and the diamagnetic susceptibility was not deducted from the experimentally  
59  
60

magnetic susceptibility. In the  $\chi_m$  vs.  $T$  plot of  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>], a magnetic phase transition occurs at  $\sim 192$  K, which is near to the thermal anomaly peak temperature of  $\sim 193$  K in DSC plot upon cooling (Figure 5b). It should be mentioned that no thermal anomaly occurs around the critical temperature of magnetic transition (which DSC plot is depicted in Figure S5).<sup>31</sup> Below  $T_C$ , the magnetic susceptibility reduces sharply and exponentially on cooling, displaying the magnetic character of a spin gap system, and reaches to the minimum ( $-4.04 \times 10^{-4}$  emu mol<sup>-1</sup>) at  $\sim 90$  K and then rises again during the further cooling process.  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] shows negative magnetic susceptibility in a wide of temperature range in LTP, demonstrating that the symmetry broken structure phase transition leads to the formation of big spin gap between the singlet ground state and the triplet magnetic excited state, as a result, the Curie-Weiss type paramagnetic susceptibility in 2–90 K contributes mainly from the diamagnetism of atoms core and the paramagnetism of magnetic impurity.

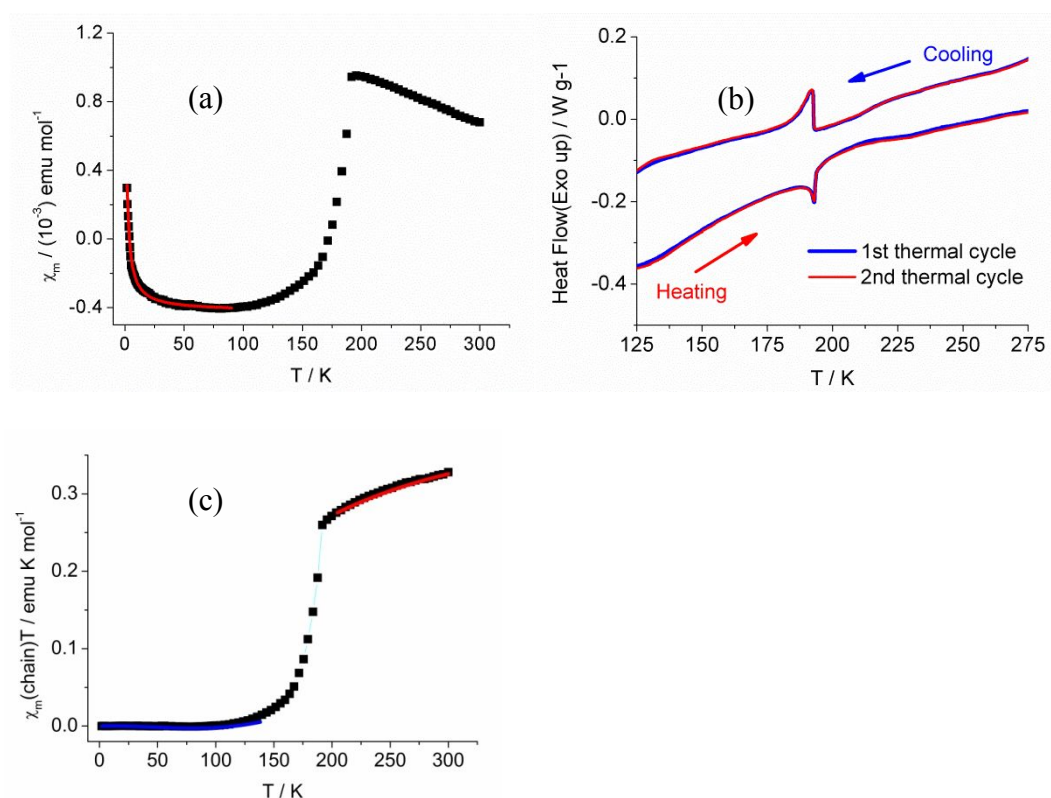

Figure 5: (a) Plot of  $\chi_m$  vs.  $T$  (black squares: experimental data; red line: theoretically reproduced curve using fitted parameters and the details referred to the main text) and

(b) DSC plots in two heating-cooling cycles (c) plot of  $\chi_m(\text{chain})T$  vs.  $T$  (black squares: experimental data; red lines: theoretically reproduced plots using fitted parameters and the details referred to the main text) for  $\beta\text{-[CN-Py][Ni(mnt)}_2\text{)]}$ .

The Eq. (1), including the atoms core diamagnetism and the magnetic impurity paramagnetism, was firstly used for analyzing the variable temperature magnetic susceptibilities in 2-90 K, and the best fit produced the Curie constant  $C = 1.83(4) \times 10^{-3}$  emu K mol<sup>-1</sup>, the Weiss constant  $\theta = -0.50(7)$  K and  $\chi_0 = -4.21(2) \times 10^{-4}$  emu mol<sup>-1</sup>. The amount of  $S = \frac{1}{2}$  uncoupled magnetic impurity, arose from the lattice defects, is estimated to be  $\sim 0.49\%$  for  $\beta\text{-[CN-Py][Ni(mnt)}_2\text{)]}$  from the fitted Curie constant. Too small Weiss constant demonstrates that the magnetic coupling between the lattice defects is really neglectable, and the  $\chi_0$  term is close to the diamagnetic susceptibility of  $\beta\text{-[CN-Py][Ni(mnt)}_2\text{)]}$ , which is estimated from tablet Pascal' constants, indicating that the temperature-independent magnetic susceptibility arises mainly from the atoms core diamagnetism.

$$\chi_m = \frac{C}{T - \theta} + \chi_0 \quad (1)$$

Since a phase transition does not alternate the lattice defects and the diamagnetism of atoms core, the paramagnetic susceptibility  $\chi_m(\text{chain})$ , contributed from the 1D  $S = \frac{1}{2}$   $[\text{Ni(mnt)}_2]^-$  stack, in both LTP and HTP is achieved by subtracting the diamagnetism and magnetic impurity from the experimental  $\chi_m$  term. The  $\chi_m(\text{chain})T$  as a function of temperature is then plotted in Figure 5c. In HTP, the  $\chi_m(\text{chain})T$  value gradually reduces as the temperature decreases, revealing the existence of AFM coupling between the nearest neighboring spins within the  $S = \frac{1}{2}$   $[\text{Ni(mnt)}_2]^-$  stack, and the  $\chi_m(\text{chain})T$  value at 300 K is  $\sim 0.328$  emu K mol<sup>-1</sup>, which is slight less than  $0.375$  emu K mol<sup>-1</sup> calculated from an isolated  $S = \frac{1}{2}$  spin-only system. In LTP, the  $\chi_m(\text{chain})T$  value is close to zero at the temperatures below 90 K, indicating that the ground state is nonmagnetic singlet state.

In the  $S = \frac{1}{2}$  Heisenberg alternating linear chain system, the spin Hamiltonian is written as

$$\hat{H} = -2J\sum_{i=1}^{n/2}(\hat{S}_{2i-1}\hat{S}_{2i} + \alpha\hat{S}_{2i}\hat{S}_{2i+1}) \quad (2)$$

where the symbol  $J$  represents the magnetic exchange constant between a spin and its left neighbor and  $\alpha J$  represents the magnetic exchange constant between a spin and its right neighbor. For an AFM coupling system ( $J < 0$  and  $0 \leq \alpha \leq 1$ ), extremely, the alternating linear chain model is simplified to the dimer model when  $\alpha = 0$  and changed to the uniform linear-chain model if  $\alpha = 1$ .<sup>41-43</sup> Deduced from the spin Hamiltonian in Eq. (2), the  $\chi_m(\text{chain})$  as a function of temperature in a Heisenberg  $S = \frac{1}{2}$  AFM linear chain, deduced from the cluster approach, can be written in the form below,

$$\chi_m(\text{chain}) = \frac{Ng^2\mu_B^2}{k_B T} \cdot \frac{A + BX + CX^2}{1 + DX + EX^2 + FX^3} \quad (3)$$

in Eq. (3),  $X = |J|/k_B T$ , and one set of parameters A-F is valid for the regular linear spin chain when  $k_B T/|J| \geq 0.5$ ,  $J \leq 0$ ,<sup>42</sup>  $k_B T_{\max}/|J| = 1.282$  and  $\chi_{\max}|J|/Ng^2\mu_B^2 = 0.07346$ ;<sup>43</sup> in the case of the irregular linear spin chain, two sets of A-F are valid when  $k_B T/|J| \geq 0.5$ ,  $J \leq 0$ , amongst them, one set of parameters A-F is usable in the case of  $0 \leq \alpha \leq 0.4$  and another one is valid for  $0.4 < \alpha \leq 1.0$ .<sup>42,43</sup>

On the basis of the crystal structure and magnetic susceptibility analysis in HTP, the magnetic behavior in HTP was analyzed using the magnetic coupling model of a regular  $S = \frac{1}{2}$  Heisenberg AFM linear chain, and the best fit for the  $\chi_m(\text{chain})$  data in 203.7-300 K gave the parameters of  $J = -86(9)$  K with  $g = 2.2$  fixed. The theoretically reproduced  $\chi_m(\text{chain})$ - $T$  plot is presented in Figure 5c (red line), which matches with the experimental data.

In LTP, the magnetic susceptibility of chain was fitted using the  $S = \frac{1}{2}$  Heisenberg alternating linear chain model, and the best fits for the  $\chi_m(\text{chain})$  data in 1.99-139.7 K yielded the parameters of the averaged  $J = -379(8)$  K, the alternating constant  $\alpha = 0.190(1)$  with  $g = 2.2$  fixed. The theoretically produced  $\chi_m(\text{chain})$ - $T$  plot is displayed in Figure 5c (blue line), which is in agreement with the experimental data. The  $\delta$  constant in the alternating chain in LTP is calculated as  $\delta = (1-\alpha)/(1+\alpha) \approx 0.681$ , and the spin gap was further estimated as 568 K using the equation of  $\Delta(\delta) \approx 2|J|\delta^{3/4}$ .<sup>44</sup>

1  
2  
3  
4 The analyses of both crystal structure and magnetic property revealed that  
5  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] is a 1D Heisenberg  $S = \frac{1}{2}$  AFM linear chain system, and the  
6 magnetic transition at  $\sim 192$  K is a spin-Peierls-type transition, but not a Peierls  
7 transition, and the alternating current conductivity measurement further supports this  
8 conclusion. As shown in Figure S6, the plots of conductivity against temperature  
9 indicate that the  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] phase not only has rather low conductivity, but  
10 also shows no sizable conductivity change around the critical temperature of magnetic  
11 transition (i.e., no metal to insulator transition), therefore, the  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>]  
12 phase is a magnetic insulator. Additionally, in previous study for a spin-Peierls  
13 compound, [NO<sub>2</sub>-Py][Ni(mnt)<sub>2</sub>] (NO<sub>2</sub>-Py<sup>+</sup> represents 1-(4-nitrobenzyl)pyridinium)  
14 with spin-Peierls transition temperature of  $\sim 182$  K,<sup>45,46</sup> we found that the nonmagnetic  
15 compound, [NO<sub>2</sub>-Py][Au(mnt)<sub>2</sub>], shows the same structure as that of spin-Peierls  
16 compound [NO<sub>2</sub>-Py][Ni(mnt)<sub>2</sub>] in HTP, however, no structure phase transition occurs  
17 in [NO<sub>2</sub>-Py][Au(mnt)<sub>2</sub>] even at  $\sim 100$  K, demonstrating that the symmetry-broken  
18 structure phase transition observed in [NO<sub>2</sub>-Py][Ni(mnt)<sub>2</sub>] arises from the spin-lattice  
19 interactions. The further investigations were done for the crystal structure, magnetic  
20 susceptibility and heat capacity of [NO<sub>2</sub>-Py][Au<sub>x</sub>Ni<sub>1-x</sub>(mnt)<sub>2</sub>] ( $x = 0.01-0.73$ ) solid  
21 solutions, which reveal the spin-Peierls transition vanishing in the heavier doped  
22 system ( $x > 0.27$ ), demonstrating that the magnetostructural phase transition in  
23 [NO<sub>2</sub>-Py][Ni(mnt)<sub>2</sub>] is the intrinsic feature of  $S = \frac{1}{2}$  Heisenberg AFM linear chains.  
24  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] shows the same crystal structures as that of [NO<sub>2</sub>-Py][Ni(mnt)<sub>2</sub>]  
25 with rather similar unit cell parameters in both regular chain HTP and dimerized chain  
26 LTP,<sup>45,46</sup> and the magnetostructural phase transition in  $\beta$ -[CN-Py][Ni(mnt)<sub>2</sub>] arises  
27 mainly from spin-lattice interaction of magnetic chains.

## 50 Conclusion

51  
52 In summary, we successfully achieved a new kinetically preferred polymorph of  
53 charge-transfer salt 1-(4-cyanobenzyl)pyridinium bis(maleonitriledithiolato)nickelate.  
54 The new polymorph shows a fascinating magnetic phase transition at  $\sim 192$  K  
55 associated with a symmetry broken structure phase transition. In HTP, both anions  
56 and cations form regular stacks, respectively, and the new polymorph features  
57  
58  
59  
60

1  
2  
3 magnetically as a regular  $S = \frac{1}{2}$  Heisenberg AFM linear chain system. In LTP, the  
4 anion and the cation stacks are dimerized, leading to a spin gap opening with  
5 nonmagnetic ground state. As a result, the magnetic phase transition occurring in the  
6 new kinetically preferred polymorph shows the typical character of a spin-Peierls-type  
7 transition and the magnetic-lattice interactions of magnetic chains is the driving force  
8 of the magnetostructural phase transition in this spin system.

52  
53 39. Notes: As shown in Figure S5, the Ni(1) atom locates at a general site, its two  
54 neighbors Ni(1)#1 and Ni(1)#2 atoms in an anion stack are generated via the  
55  
56  
57  
58  
59  
60

1  
2  
3  
4 symmetric transforms #1 = x, 0.5-y, -0.5+z and #2 = x, 0.5-y, 0.5+z. If the  
5  
6 fractional coordinates of Ni(1) is defined as (x, y, z), then two neighbors Ni(1)#1  
7  
8 and Ni(1)#2 have the fractional coordinates of (x, 0.5-y, -0.5+z) and (x, 0.5-y,  
9  
10 0.5+z), respectively. The distances of Ni(1)...Ni(1)#1 and Ni(1)...Ni(1)#2 are  
11  
12 correspondingly equal to the moduli of the vectors of (0, 0.5-2y, -0.5) and (0,  
13  
14 0.5-2y, 0.5). Obviously, the vectors of (0, 0.5-2y, -0.5) and (0, 0.5-2y, 0.5) locate  
15  
16 on the YZ-plane of the crystallographic coordinate system. Since two-dimensional  
17  
18 coordinate system (Y-O-Z) is orthogonal in the monoclinic system, the lengths of  
19  
20 the vectors should be given by  $|\text{Ni}(1)\dots\text{Ni}(1)\#1| = |(0, 0.5-2y, -0.5)| = \{0^2 +$   
21  
22  $(0.5-2y)^2 + (-0.5)^2\}^{1/2}$  and  $|\text{Ni}(1)\dots\text{Ni}(1)\#2| = |(0, 0.5-2y, 0.5)| = \{0^2 + (0.5-2y)^2$   
23  
24  $+ (0.5)^2\}^{1/2} = \{0^2 + (0.5-2y)^2 + 0.5^2\}^{1/2}$ . Thus,  $|\text{Ni}(1)\dots\text{Ni}(1)\#1| = |\text{Ni}(1)\dots\text{Ni}(1)\#2|$ ,  
25  
26 moreover, the distance of Ni(1)#1...Ni(1)#2 =  $|\text{Ni}(1)\#1\dots\text{Ni}(1)\#2| = |(0, 0, 1)|$ ,  
27  
28 namely, the Ni(1)#1...Ni(1)#2 distance is equal to the crystallographic cell length  
29  
30 of *c*-axis.

### A new kinetically preferable polymorph of 1-(4'-cyanobenzyl)pyridinium bis(maleonitriledithiolato)nickelate with spin-Peierls type transition

Guo-Jun Yuan, Dong-Sheng Shao, Qiu Ren, Fei-Yan Feng, Hao Yang, Lifeng Wang, Xiao-Ming Ren

The unpredictably achieved  $\beta$ -phase polymorph of 1-(4'-cyanobenzyl)pyridinium bis(maleonitriledithiolato)nickelate is kinetically preferred and exhibits a spin-Peierls type transition.
